Introduction

Pancreas

The pancreas plays a key role in humans serving as both an endocrine and exocrine gland in the digestive system (1). The pancreas extends across the abdomen, and has an enlarged head region as well as a tail portion. Located behind the stomach and partially connected to the duodenum, the pancreas acts to aid in digestion as well as adjusting gastrointestinal hormone levels. The exocrine portion of the pancreas utilizes zymogens and bicarbonate in order to assist in digestion and neutralization, respectively (2). As to be expected, the endocrine pancreas aids in regulating hormone levels to allow for metabolic homeostasis.

Comprising part of the small intestinal tract, the pancreas is made up of different epithelial cell types, which have very specific functions. Various genes have been associated with the formation and regulation of the pancreas such as Sox 9, Neurog3, and Ptf1a (1). The exocrine region of the pancreas is composed of duct cells and acinar cells which function to produce zymogens (2). Duct cells deliver zymogens and bicarbonate for activation in the duodenum, and subsequently digestion of food (2). In the endocrine portion of the pancreas there are large collections of epithelial cells called islets of Langerhans (3). The islets of Langerhans contain several types of hormone-secreting cells including α, β, γ, ε, and pancreatic polypeptide-secreting cells (3). β cells have received much attention in research because these cells produce insulin, and are implicated various forms of diabetes (3). Figure 1 depicts a cartoon schematic of the pancreas, pancreatic cells and surrounding organs (open
Pancreatitis

There exist two divisions of pancreatitis: acute and chronic, with autoimmune pancreatitis falling under the chronic distinction (4). Pancreatitis can arise due to damage of the pancreas, infection, as a result of alcoholism and smoking or due to genetic mechanisms (2). Acute pancreatitis is diagnosed in 210,000 Americans every year, and can range from mild to lethal in severity, with 20% of cases resulting in death caused by necrotizing disease (5). The condition is caused by the pancreas using its own proteases to digest itself. It remains unknown whether or not trypsin and cholecystokinin are directly responsible for this autodigestive damage (6). Acute pancreatitis results in symptoms of epigastric pain, vomiting, and nausea, along with markedly increased amylase and lipase levels (6).

To determine the prognosis, the systemic inflammatory response (SIRS) and the Bedside Index for Severity of Acute Pancreatitis (BISAP) tests are employed (5). Currently, there are not many treatments to combat the disease itself, but supportive treatments such as fluid resuscitation, and enteral feeding help to maintain health in the patient (5).

Chronic pancreatitis typically originates from acute pancreatitis although not all patients continue on to develop chronic pancreatitis. This recurrent form of pancreatitis is marked by fibrosis, loss of islet and acinar cells in the pancreas, and inflammation (7). Patients who develop acute pancreatitis by smoking or consuming alcohol are more likely to develop the chronic form of pancreatitis (7). Diagnosing chronic pancreatitis can be attained through various imaging tests (MRI, EUS, CT), and patients typically present with great abdominal pain similar to that of acute pancreatitis (7). Like acute pancreatitis, treating and managing chronic pancreatitis is very difficult; Many

Figure 1 A cartoon depiction of the pancreas and surrounding organs (open access, no copyright)
times even after therapy, patients still retain symptoms (7). In order to manage chronic pancreatitis, abstinence from alcohol, pancreatic enzymes, analgesics, or sometimes narcotics and opioids are employed (7).

Autoimmune pancreatitis typically presents in middle-aged and elderly males, accompanied with obstructive jaundice, diabetes mellitus, and epigastric discomfort (8). Three criteria are used to diagnose autoimmune pancreatitis; Enlargement of the pancreas and narrowing of the main pancreatic duct, elevated levels of autoantibodies, and lymphoplasmacytic infiltration and fibrosis (8). Although rare, it has also been found that autoimmune pancreatitis can be misdiagnosed as, or found in conjunction with pancreatic cancer. These findings make it rather difficult for clinicians to determine the true diagnosis of the patient, so tests to differentiate the conditions must be used (4).

Pancreatic cancer

According to the American Cancer Society, in 2013, there will be 45,220 cases of pancreatic cancer diagnosed in US, with 38,460 dying of this devastating cancer (9). Pancreatic cancer remains one of the deadliest cancer types, with a five-year survival rate of about 5% (10). Pancreatic cancer is notorious for being asymptomatic, which then allows the disease a greater ability to metastasize to other organs before it is ever diagnosed. This particular type of cancer arises due to several factors, including environmental, genetic, and pathological causes (11). Specifically, a history of smoking, increased body mass index, family history of pancreatic cancer, alcoholism, pancreatitis, and diabetes mellitus are all factors, which increase the risk of obtaining pancreatic cancer (10). There are various forms of pancreatic cancer, which affect both the endocrine and exocrine pancreas systems. The most common cancerous tumor in the pancreas is invasive ductal adenocarcinoma, and typically retains the title of pancreatic cancer (11). Neuroendocrine tumors in the pancreas may also arise, but are much less prevalent (12). Neuroendocrine tumors result due to an excess in pancreatic hormone levels, and treatment must be established to correct the excess in that particular hormone, as well as possibly identifying the presence of an inherited disease that caused this excess (12). Currently, due to the asymptomatic nature of pancreatic cancer, early diagnosis remains a challenge. However, once the diagnosis is made, patients typically undergo various treatments such as chemotherapy, chemoradiotherapy, possibly surgical resection of the tumor, as well as other supportive therapies (4,9,10,12).

Histamine

The biogenic monoamine histamine is one of the most intensely studied molecules in the biological system (13). Histamine is known to induce broad spectrum of biological activities including cell proliferation, differentiation, regulation of gastrointestinal function, and modulation of immune responses (13). Histamine is a low molecular weight amine synthesized exclusively by L-HDC that is expressed in numerous cells throughout the body including gastric-mucosa, parietal, and mast cells (14). After histamine is formed by HDC it is rapidly stored or degraded (15).

Histamine exerts its biological effects by interacting with four G protein-coupled (GPCR) receptors, i.e., H1HR, H2HR, H3HR, and H4HR (15). Activating or inhibiting the HRs triggers downstream signaling pathways to elicit immune-modulatory and pro-inflammatory cellular responses (15). H1HRs main signal is induced by ligand binding and activation of phospholipase C-generating inositol 1, 4, 5-triphosphate and 1, 2-diacylglycerol (DAG) leading to increased cytosolic Ca2+ (13,16,17). The H2HR is coupled to adenylate cyclase and to phosphoinositide secondary messenger system via separate GTP-dependent mechanisms (18,19). Histamine is a strong stimulant of cAMP accumulation in many cells, and H2HR-dependent signaling of histamine is typically mediated through cAMP (18,19). In contrast, H3HR activation triggers inhibition of cAMP formation, accumulation of Ca2+ and stimulation of mitogen-activated protein kinase (MAPK) (20,21). H4HR is expressed in many areas of the body including intestinal tissue, basophils, and mast cells (13,22). Similar to H3HR, H4HR signaling mechanisms triggers an inhibition of adenyl cyclase and downstream of cAMP response elements as well as activation of MAPK (22,23).

Figure 2 depicts the generally acknowledged signaling of the histamine/histamine receptor axis [used with permission from Shahid, et al., “Histamine, Histamine Receptors, and Their Role in Immunomodulation: An Updated Systematic Review” The Open Immunology Journal, 2009;2:9-41 (open access journal)].

The role of histamine during biliary damage and biliary cancer has been extensively studied (14,15,17,18,20,21,23). Because the biliary tract and pancreas share similar pathological, phenotypical and biological features (24) it is likely that histamine, the histamine receptors and the synthesis of histamine by HDC are all important in
the regulation of pancreatic diseases like pancreatitis and pancreatic carcinoma.

**Histamine and pancreatitis**

As stated above, while most cases of acute pancreatitis are non-progressive, recurrent episodes may lead to chronic pancreatitis, which is also a very challenging disease (25). As the pathophysiological causes of acute and chronic pancreatitis gradually become revealed to us, it is hopeful that their treatments will become more successful. However, the biological basis of pain and the mechanisms underlying the pathogenesis of acute and chronic pancreatitis is still poorly understood (26-28). Recent findings indicate that the activation of granulocytes and macrophages in pancreatitis results in the release of a number of cytokines and inflammatory mediators and an important inflammatory mediator, the mast cell, secretes histamine as well as other chemotactic molecules and inflammation activators (29-31). Mast cells have been implicated in the pathogenesis of pain in other conditions and some have hypothesized that mast cells and histamine secretion play a role in the pain of chronic pancreatitis, which is characterized by mononuclear inflammatory cell infiltration (27,32-34). Interestingly, it has been shown that humans with painful chronic pancreatitis have an increased number of pancreatic mast cells compared to those with painless chronic pancreatitis (27).

Because histamine is produced predominantly by mast cells, it is important to consider studies involving mast cell activation and pancreatitis to analyze the resultant effects of histamine during the course of this threatening disease. It has also been argued that increased circulating histamine levels worsen distant organ injury, especially if derived from pancreatic mast cells in cases of acute and chronic pancreatitis (28,35,36). In an attempt to study the activation of pancreatic mast cells and the effects of mast cell inhibition on the activation of peritoneal and alveolar macrophages during acute pancreatitis, a recent study suggested that pancreatic mast cells are significant triggers of local and SIRS in the early phases of acute pancreatitis (37). These authors confirmed that pancreatitis resulted in increased levels of circulating histamine in plasma in both the pancreas and lung. The inhibition of mast cell degranulation with cromolyn sodium also resulted in a reduction in pancreatic myeloperoxidase (MPO) activity, indicating that this treatment reduced pancreatic inflammation (37). Several mediators released by mast cells, including histamine are increased shortly after (a few minutes) the induction of pancreatitis in their experimental models. In addition to this, administration of mast cell inhibitors results in a reduction of the local and SIRS and prevents changes in endothelial cells and vascular permeability (37). As histamine has been confirmed to be a potent vasodilator, histamine may possibly be an important factor to study in increased vascular permeability in pancreatic inflammation (28,38). There is a very large population of mast cells that resides in the periacinar space, pancreatic interstitium and mesentery and these mast cells degranulate early in acute pancreatitis (39). In three models of necrotizing disease, local increases were noted of mast-cell mediators, histamine being one of them (39). In addition, water immersion-induced stress was shown to result in the conversion of hyperstimulation mild pancreatitis into necrohaemorrhagic disease, similarly to when histamine or dimethyl PGE2 were added in a duct.

![Diagram of histamine receptors and their signaling pathways](image)
hyperpermeability model of mild pancreatitis (40). A similar pattern of increase in plasma histamine has been recorded in pancreatitis models upon exposure to water immersion stress (40,41). As acute pancreatitis can be fatal when it advances to systemic inflammation and multi-organ failure, Kempuraj et al., desired to study a mouse model of pancreatic duct ligation-induced acute pancreatitis that is associated with systemic inflammation and substantial mortality (28). These authors found using an Enzyme-Linked Immunosorbant Assay (ELISA) for in vivo mouse duct ligation-induced acute pancreatitis models, plasma histamine concentrations were increased. In concurrence with these findings, it has also been speculated that increased circulating histamine levels originating from activated pancreatic mast cells are implicated in the development of acute lung injury during acute pancreatitis (28,35,36). Zhao et al., demonstrates that pancreatitis-associated lung injury is an early-occurring and severe complication that involves a number of inflammatory cells and their products in the initiation and progress of the condition (36). While higher plasma levels of histamine were determined, the intraperitoneal administration of cromolyn (a mast cell stabilizer) reduced pancreatitis-induced systemic increase of histamine after one hour. Cromolyn was also found to prevent pancreatitis-induced pulmonary endothelial barrier dysfunction after 6 hours (36). The authors hypothesize that mast cells and histamine may play an important role in the activation of leukocytes during the initiation of pancreatitis-associated lung injury by altering phenotypes of adhesion molecules (36). Figure 3 shows immunohistochemistry for mast cells (marked by toluidine blue) in the pancreas and lung after induction of pancreatitis (B and E) and after cromolyn treatment (C and F). Degranulating mast cells were observed in the pancreas after pancreatitis induction (B) and cromolyn treatment inhibited mast cell degranulation (Reused with permission from World Journal of Gastroenterology “Pancreatic and pulmonary mast cells activation during experimental acute pancreatitis” 2010;16:3411-7).
In clinical trials, controlling histamine levels by way of receptor inhibition or mast cell stabilization has yielded mixed results. In a retrospective analysis of pancreatic exocrine insufficiency (PEI), Sander-Struckmeier et al., aimed to determine whether the efficacy of pancrelipase/pancreatin may be affected by the concomitant use of proton pump inhibitors (PPIs)/histamine-2 receptor antagonists (H2RAs) (42). PEI, which is a deficiency or absence of digestive enzyme secretion in the duodenum, is associated with many pancreatic disorders such as cystic fibrosis and chronic pancreatitis. Analyzed data from a number of clinical trials in patients having PEI indicates that the efficacy of pancrelipase/pancreatin is not affected by concomitant PPI/H2RA use and concurs with the treatment guidelines’ recommendation that acid suppression is not routinely mandated with pancreatic enzyme replacement therapy (42). Early administration of protease inhibitors has commonly been employed for the therapy of acute pancreatitis in Japan. Kohsaki et al., state that a number of clinical trials have failed to show the clinical effects of protease inhibitors and H2 receptor antagonist during the treatment of acute pancreatitis and these authors argue that well-organized clinical studies should be undertaken to assess the relative therapeutic value of these agents for acute pancreatitis (43). However, according to Abdel Aziz et al., non-enteric-coated enzyme preparations along with acid suppression (histamine-2 blockers or PPIs) have at least a modest effectiveness in treating pain caused by chronic pancreatitis and may be worth a trial in patients with less advanced disease diagnosis (44). Clearly, more work needs to be performed to fully understand the role of histamine and histamine receptors (H1-H4HRs) on the treatment strategies of pancreatitis.

**Histamine and pancreatic cancers**

Pancreatic cancer is the leading cause of cancer-related deaths worldwide due to its aggressive nature (45). For this reason, it is of great importance that we ascertain the interrelations of pancreatic cancer and discover new therapeutics to help combat this devastating disease. HDC, which converts histidine to histamine, has been an important area of study recently due to histamine’s known ability to accelerate cancerous cells into cell cycle arrest (45). In normal pancreatic islet cells, HDC is predominantly found in glucagon cells, but in pancreatic tumors, HDC was found in all types of islet cells: glucagon-, insulin-, somatostatin-, pancreatic polypeptide- and serotonin-producing enterochromaffin cells (46). Over expression of HDC has been demonstrated in various pancreatic cancer cells, but one study found that 79% (19/24) of the evaluated pancreatic tumors showed HDC expression (46,47). Based on this study, we can define HDC as an indicator of endocrine differentiation and, therefore, a potential diagnostic tool in pancreatic cancer (46).

Various other studies have been performed to evaluate how histamine carries out cellular proliferation via its G-protein coupled histamine receptors (H1-H4HR). Previous research performed on the PANC-1 cell line, which is derived from human pancreatic carcinoma and contains a mutated p53, demonstrated that these cells over express H1HR and H2HR (45). When bound to H1HR, histamine has been shown to induce PANC-1 proliferation by up regulating nerve growth factor (NGF) secretion and mRNA expression (49). These effects can be negated by pyrilamine, the H1HR antagonist, which further proves the increased proliferative effect of histamine (49). Histamine or an agonist binding to H1HR has also proven to influence PANC-1 cells into metastasis due to a decrease in cellular adhesion; which is associated with an increase in matrix metalloprotease 2 (MMP2) activity (48,50). In contrast, when H1HR and H2HR were blocked using specific receptor antagonists there was an increase in adhesion and, therefore, a decrease in cellular motility (48). Activation of H2HR in PANC-1 cells tends to have the opposite effect of H1HR activation. A study by Cricco et al., states that H2HR activation, through the binding of histamine, generates partial cellular differentiation of the PANC-1 cell line and stimulates cAMP production to inhibit proliferation (45). Bel-2, an anti-apoptotic regulator protein, may be involved in this regulation of cAMP (45). This H2HR activation also inhibited PANC-1 cell growth by moving the cells into G0/G1 phase arrest (45). Furthermore, the expression of proliferating cell nuclear antigen (PCNA) and Bax, a pro-apoptotic factor, were decreased through H2HR modulation (45,51). Additional research done on the various histamine receptors has proven that H3HR stimulation increases cellular proliferation by regulating the cell cycle, but that H4HR stimulation diminishes pancreatic tumor growth (52,53). The pathological and biological functions of H3HR and H4HR activation...
in pancreatic tumors are vague and require further investigation in order to be clearly defined.

Currently, mast cells have been of great interest in the studies of pancreatic cancer as well (54). Mast cells are ubiquitous and found throughout all tissues of the human body and contain many cytoplasmic granules that, when stimulated, are able to release considerable quantities of histamine into the surrounding microenvironment (54). Mast cells have other roles, but their release of histamine is what draws them into the interest of this review. In general, mast cell infiltration is increased in cases of pancreatic cancer when compared to normal pancreatic tissue (55). This same study demonstrated how PANC-1 cells, when in the presence of mast cell conditioned media, were accompanied with an influx of mast cells; Which leads to increased pancreatic cancer cell migration, proliferation, and invasion (55). Conversely, this infiltration did not have an effect on normal pancreatic tissues (55). This increase in mast cell number can be an indicator of higher-grade pancreatic adenocarcinoma and, therefore, can be correlated with poorer prognosis for the patient (54,55). The exact pathological and physiological role of mast cells and histamine secretion in pancreatic carcinoma is unclear and requires further research.

**Clinical studies in pancreatic cancer**

Currently, 5-6% of pancreatic cancer patients with non-resectable disease have an estimated survival rate of 5-years, but chemotherapy resistant patients have a median survival time of <6 months (56,57). Due to its poor prognosis and aggressive nature pancreatic cancer has prompted many research facilities to perform clinical trials to help determine a productive treatment method for this disease. For the past 10-15 years the main form of chemotherapy treatment for advanced and metastatic cancer was the use of gemcitabine, an anti-metabolite (56). Generally, gemcitabine is a favorable treatment in patients that have a poor performance status (56). Five recent clinical trials tested the efficacy of gemcitabine by administering it to different sets of patients; four trials administered it as a fixed dose rate of 10 mg/m²/min, while one trial administered it as a standard infusion rate over 30 minutes (56,58-61). The data from all five of these trials gave a median response rate (RR) of 23%, a median progression-free survival (PFS) of 4 months, and an overall survival (OS) of 6 months (56).

Research has suggested that there may be a survival benefit in first-line treatment when erlotinib, a tyrosine kinase inhibitor, is combined with gemcitabine (56,62). One trial treated patients in a 1:1 ratio with either a combination of erlotinib and gemcitabine or gemcitabine together with a placebo (62). The results from this study concluded that OS was significantly prolonged with the erlotinib/gemcitabine treatment compared to gemcitabine with the placebo (6.24 vs. 5.91 months, respectively) (62). Overall first-year survival was also greater with the combined treatment (23% vs. 17%), but there tended to be more adverse side effects with the combined treatment (erlotinib and gemcitabine) when compared to gemcitabine with the placebo (62).

Other studies have suggested the use of gemcitabine in conjunction with platinum agents as a potential treatment in the first-line setting of advanced pancreatic cancer (56,63-65). When analyzing the results from gemcitabine with platinum agents there tended to be an improvement in RR and PFS (P=0.006 and 0.059, respectively), but no significant improvement in OS (P=0.1) when compared to other methods of treatment (56). Gemcitabine is not the only compound that has been suggested to be used with platinum agents. Some research has suggested the use of the pyrimidine analog, 5-fluorouracil (5-FU) with platinum agents as well (56). Recently, 8 trials studied the effectiveness of 5-FU with oxiplatin, a platinum based alkylating agent, and 2 trials tested 5-FU with cisplatin, a platinum containing drug that cross-links DNA (56,62,66-72). When analyzing the data from these 8 clinical trials, the 5-FU combined with a platinum agent had a median PFS of 2.9 months and a median OS of 5.7 months (56,62,66-72). When compared to the treatments stated earlier, it seems as if the combination of 5-FU with platinum containing agents is less efficient in terms of survival benefit (56).

**Future studies and concluding statement**

Throughout this article we have aimed to highlight the characteristics of pancreatitis, pancreatic cancer, and histamine’s role in the progression and development of these diseases. When viewing current literature that discusses the involvement of histamine in various forms of pancreatitis we can see that histamine and mast cell secretion tightly regulate inflammation, which can ultimately lead to endothelial cell destruction. Being able to block this pro-inflammatory signaling pathway via mast cell degranulation inhibition may decrease the damaging effects that histamine is able to enact on the pancreas. Histamine has also been labeled as a vasodilator in pancreatitis, but its
exact function in this area requires further investigation. In terms of clinical trials, some work on the treatment of acute pancreatitis using protease inhibitors and an H2 receptor antagonist were ineffective in terms of prevention and replacement therapy, but were successful in relieving pain in early developed acute pancreatitis. Clinical trials on histamine influence in pancreatitis are few and far between and thus require additional studies. Histamine's regulation of pancreatic cancer is more convoluted and confusing than it is in pancreatitis in general. When working through its H1HR and H3HR receptors histamine has demonstrated pro-proliferative and metastatic abilities in the PANC-1 cell line, but when bound to H2HR or H4HR histamine has proven to be anti-proliferative through G0/G1 cell cycle arrest, the diminishment of tumor growth, and generation of partial cellular differentiation. Recent clinical trials on pancreatic cancer have been valuable in terms of generating treatment options that successfully help to prolong life, but no current trials have been performed with histamine-, mast cell-, or histamine receptor-related therapies. For this reason, clinical studies on the manipulation of histamine through various signaling molecules, such as mast cells, HDC, and H1-H4HR, need to be developed to help determine if this area of study could be beneficial to the lives of future patients. The future of histamine in prevention, diagnosis and therapy of pancreatic diseases is unknown and open to evaluation and experimentation.
